(Received 20 June 1985; Accepted 19 December 1985)

Abstract—Aqueous acetonitrile solution-phase photoincorporations of six polychlorobenzenes (PCBzs) into some humic model monomers such as benzoic acid, benzaldehyde, vanillic acid, vanillin, syringic acid and syringaldehyde were investigated using UV light centered at 300 nm. All the PCBzs studied except hexachlorobenzene yielded photoproducts by the reaction of the polychlorophenyl radicals with the individual humic monomers. Chlorophenylation of humic model monomers occurred in the case of benzoic acid and benzaldehyde; substituted polychlorodiphenyl ethers were also formed when monomers containing a phenolic OH group were present. Furthermore, the irradiation of 1,2,4,5-tetrachlorobenzene in solution in the presence of vanillic acid produced monochloro- and dichloromethoxydibenzofuran carboxylic acids in addition to the other photoincorporated products.

Keywords—Photoincorporations Polychlorobenzenes Humic model monomers Substituted polychlorinated biphenyls Substituted polychlorodiphenyl ethers Substituted polychlorinated dibenzofurans

INTRODUCTION

Polychlorobenzenes (PCBzs), compounds of anthropogenic origin, have been found in almost every aquatic environment worldwide [1-4], as have natural macromolecules such as humic substances including fulvic acids, humic acids and humins [5-8].

Previously, we reported that photoproducts such as polychlorobiphenyls (PCBs) with $2n-1$ and $2n-2$ Cl atoms are formed during the irradiation ($\lambda > 285$ nm) of solutions of chlorinated benzenes ($\text{Cl}_n=\text{Bzs}$), viz., 1,3,5- $\text{Cl}_3\text{-Bz}$ [9], and $\text{Cl}_4\text{-Bzs}$ and $\text{Cl}_5\text{-Bz}$ [10] in acetonitrile-water. It appears reasonable to expect that when relatively stable chlorophenyl radicals are photochemically generated in natural waters they may react with the abundantly available natural organic matter. In view of the complex nature of humic sub-

stances [5-8] it was preferable for us to first investigate these types of reactions with humic model monomers.

Humic substances (fulvic acids, humic acids and humins) are complex materials; more than 150 compounds in three major classes—aliphatics, substituted benzenes and polycyclic aromatic hydrocarbons—have been reported as products obtained through chemical degradation and physical separation techniques (see Table III in ref. 5). The second class of the approximately 80 humic monomers includes benzene (poly) carboxylic acids, vanillin, vanillic acid, syringaldehyde, syringic acid and several other benzene derivatives [5-7]. We therefore decided to include some of these monomeric degradation products in our studies of the photoincorporation of PCBzs into humic monomers.

As cited in the recent protocol guidelines for the investigations of photochemical fate of pesticides in water, air and soils [11], the levels of pes-

ticides (and environmental pollutants) in aquatic systems recommended for the evaluation of kinetics frequently do not permit the observation, isolation and identification of the photoproducts arising from the test chemicals. For instance, the use of two sunlight actinometers, namely, *p*-nitroanisole (7.9 μM)/pyridine and *p*-nitroacetophenone (20 μM)/pyridine in water (both developed and evaluated by Dulin and Mill [12]), has been frequently noted in the literature [11]. The photoproducts, however, have not been reported for either of these chemical actinometers. Similarly, Choudhry and Webster [13; Choudhry and Webster, manuscript submitted for publication] were not able to observe any photoproduct arising from polychlorinated dibenzo-*p*-dioxins (PCDDs) (approximate 1 μM levels) in aqueous acetonitrile during studies of the kinetics and quantum yields of these pollutants. According to the above-mentioned guidelines [11], it is necessary, however, that as many as possible of the laboratory degradation products be qualitatively and quantitatively identified, even though they may not be present at detectable levels in actual field studies, so that a mechanism of the degradation of a pollutant can be established. For this purpose, the solubility of the test pesticide (environmental chemical) in water may need to be increased several-fold, using larger volumes of the cosolvent, e.g., CH_3CN , up to 50% (v/v). In view of the guidelines and our previous experience (see ref. 18, and preceding articles of this series), we have used increased proportions of cosolvent as required.

Humic substances have been reported to sensitize and quench the photolysis of several environmental pollutants [5,14–17]; however, no report has been published to date on the photochemical incorporation of these compounds with humic macromolecules. Recently, Choudhry et al. [2] reported that PCBzs containing four, five and six chlorine substituents react photolytically in $\text{CH}_3\text{CN-H}_2\text{O}$ in the presence of phenol to produce polychlorinated dibenzofurans (PCDFs) in an approximate 1% chemical yield. Because of our continuing interest in the environmental photolytic fate of chlorinated aromatic pollutants [18], we undertook further study of photochemically induced reactions of chlorobenzenes with humic-type monomers. This article reports our laboratory investigations of the photointeraction of six PCBzs with selected humic model monomers in aqueous acetonitrile at wavelengths typically used in environmental photochemistry.

METHODS

Substrates and solvents

The source of PCBzs 1 through 6 and solvents have been described elsewhere [10]. Benzoic acid (7), benzaldehyde (8), vanillic acid (9), vanillin (10), syringic acid (11) and syringaldehyde (12) were purchased from Aldrich.

Preparation of solutions

Stock solutions of chlorobenzenes and humic monomers were prepared in acetonitrile. The previously reported method [10] was utilized for the preparation of sample solutions of all PCBzs (1 to 6) containing each humic model monomer in water-acetonitrile. For the solutions containing humic monomer 7, the $\text{H}_2\text{O}:\text{CH}_3\text{CN}$ ratios (v/v) were as follows: 1:1 for PCBzs 1 to 3, 4:6 for PCBzs 4 and 5 and 1:9 for PCBz 6 (Table 1). In the case of monomer 8, the following $\text{H}_2\text{O}:\text{CH}_3\text{CN}$ ratios (v/v) were used: 1:1 for PCBzs 2 to 5 and 1:9 for PCBz 6 (Table 2). The photolysis sample solutions of $\text{Cl}_4\text{-Bz}$ 4 containing humic monomers 9 to 12 (Table 3) were prepared in 1:1 (v/v) $\text{H}_2\text{O}:\text{CH}_3\text{CN}$. During the photoinduced reactions of PCBzs with monomer 7 (Table 1), the concentrations of chlorobenzenes 1 to 6 were 1.00 mM and each solution contained 5.00 mM benzoic acid. Similarly, in the case of benzaldehyde (8), 1.00 mM solutions of PCBzs 2 to 6 were used, each solution containing 5.00 mM aldehyde 8 (Table 2). For the studies on the photochemical interactions of 1,2,4,5- $\text{Cl}_4\text{-Bz}$ (4) with vanillic acid (9), vanillin (10), syringic acid (11) and syringaldehyde (12), the concentrations (mM) were as follows: 4: 1.03 and 9: 4.93; 4: 1.03 and 10: 5.01; 4: 1.11 and 11: 5.06; 4: 1.08 and 12: 5.00 (Table 3).

Ultraviolet spectra

UV spectral data for 1,3,5- $\text{Cl}_3\text{-Bz}$ (1) and humic model monomers 7 to 12, documented in Table 4, were recorded on a Cary-14 double-beam spectrophotometer. Previously reported data for PCBzs 2 to 6 were also recorded on this instrument (Table 4) [2].

Irradiation equipment and experiments

Photolyses were carried out in Pyrex tubes (2.0 ml sample solution) utilizing a previously described [19] Rayonet Photochemical Reactor equipped with a merry-go-round apparatus. The Reactor was equipped with 16 RPR 3,000-Å lamps hav-

ing an energy output of 90% between 290 and 310 nm. The emission maximum of these lamps occurred at about 300 nm; the flux density was approximately 0.525 mW/cm². Samples were not deaerated prior to photolysis. It should be noted that Pyrex transmits less than 1% of radiations below 290 nm [19].

Extraction procedures. For the irradiation of PCBzs in the presence of humic model monomers, 1.00 ml *n*-hexane containing 0.100 mM 4,4'-dichlorobiphenyl as an internal standard was added to each photolyzed sample as well as to the corresponding unphotolyzed samples. The samples were then shaken well and the *n*-hexane layer separated from the H₂O-CH₃CN layer. The *n*-hexane extracts of the samples were treated with an etheric solution of diazomethane (CH₂N₂). After 24 h, a few drops of *n*-nonane was added as a keeper to the hexane-ether solutions, which were then reduced to approximately 0.2 ml under a stream of dry nitrogen.

Gas chromatography. Quantitative analyses of all *n*-hexane extracts were carried out as previously described [10] on a Hewlett-Packard GC equipped with a flame ionization detector. For photolyses of PCBzs 1 to 6 in solutions containing humic model monomers 7 to 12, the extent of disappearance of the initial PCBz was determined using column A (5% Carbowax 20 M); column C (3% silicone OV 101) was used for the quantitation of the photoincorporated products listed in Tables 1 and 2. The products (Tables 1 and 2) were quantified by previously described techniques [2,9,10,18,19] that used the amount of undecomposed initial PCBz present in a photolyzate. The chemical yields of these photoproducts were calculated from the amount of phototransformed initial chlorobenzene. For the analyses of the Cl₄-Bz 3 and 4 samples, column B (10% Carbowax 20 M) was also used. GC conditions have been described elsewhere [10]. Tetrachlorobenzenes 3 and 4 are only resolvable on column B [10].

Gas chromatography-Mass spectrometry. All photoproducts (documented in Tables 1, 2 and 3) were qualitatively characterized on a Hewlett-Packard GC-MS 5894 equipped with a fused-silica capillary column coated with CP-SIL 5 (operating conditions of this GC-MS were as reported previously [10]).

Identification of photoproducts

Pending the availability of authentic standards, structures of the photoproducts in Tables 1 to 3

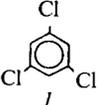

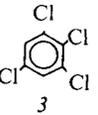

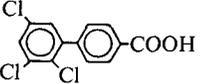

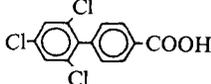

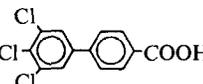

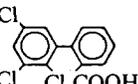

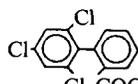

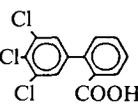

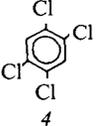

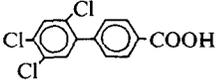

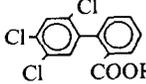

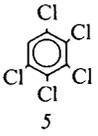

were determined by interpretation of GC-MS data. The mass spectra of all chlorinated photoproducts (Tables 1 to 3) showed fragments (m/e) formed through the loss of 1 Cl, 2 Cl, and so on, atom(s) from the parent molecular ions (M⁺). In these mass spectra, the ion clusters for M⁺ and fragments containing Cl had relative abundances characteristic of the correct number of Cl atoms [20]. Moreover, the mass spectra of the methylated derivatives of the polychlorophenylbenzoic acid photoproducts arising through the photoincorporations of PCBzs 1 to 5 into humic monomers 7 and 8 (Tables 1 and 2 showed m/e values such as M-31 (M-OCH₃) and M-59 (M-COOCH₃)) confirmed the presence of COOCH₃ groups in these derivatized compounds. The M-31 and M-59 fragments were also present in the spectra of the photoproducts recorded in Table 3. Likewise, in addition to the above-described features, the mass spectra of the polychlorodiphenyl ether products containing OCH₃ and COOCH₃ (after methylation) substituents and those of the methyl ester of the dibenzofuran carboxylic acid 24 and 25 (documented in Table 3) revealed fragments with m/e values of M-63, indicative of the loss of COCl groups from the parent molecular ion.

RESULTS AND DISCUSSION

The photoreactions of approximate 1 mM concentrations of polychlorobenzenes 1 to 6 in water-acetonitrile mixtures containing individual compounds 7 to 12 (approximately 5 mM) at λ_{max} of 300 nm are documented in Tables 1 to 3. The tables include only those products formed through the incorporation of photolytically generated polychlorophenyl radicals (discussed below) into humic monomers, viz., Reactions 1 and 2 (Fig. 1), where *n* = 3-5 and R = COOH, CHO, OCH₃, OH, and so on.

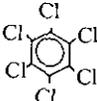

For benzoic acid (7) and benzaldehyde (8), Tables 1 and 2 also record chemical yields calculated on the basis of photoconverted initial PCBz. For instance, 14.7, 8.2, less than 2.4 and less than 2.4% of the decomposed 1,3,5-Cl₃-Bz (1) was photoconverted into four isomers of dichlorophenylbenzoic acid when the solution of substrate 1 was exposed for 16.5 h in the presence of monomer 7 (see Table 1). Quantitative analytical techniques (see Methods) failed to separate some components of the photolyzates obtained by the photolyses of Cl₄-Bz 4 in solutions containing vanillic acid (9), vanillin (10) and syringic acid (11) for 16 h; therefore, the products of these

The CH₃CN:H₂O ratios (v/v) were 1:1 for PCBzs 1 to 3 and 3:2 for PCBzs 4 and 5, whereas for hexachlorobenzene (6), CH₃CN:H₂O (9:1) was the solvent system. Concentrations of PCBzs 1 to 6 were 1.00 mM, and each sample solution contained 5.00 mM humic monomer 7.

^aNumber of isomers, if any, and their percentages of total product given in parentheses.

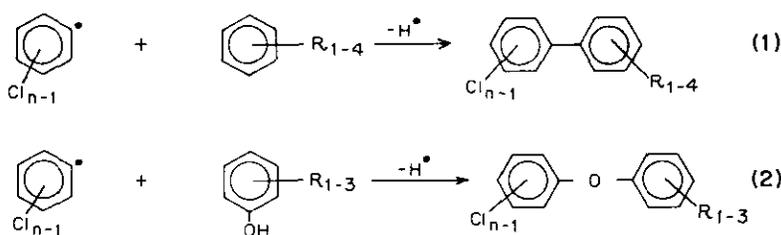

Fig. 1. Reactions by which photolytically generated polychlorophenyl radicals are incorporated into humic monomers.

photoreactions were not quantified (Table 3). However, the chemical yields of the products documented in Table 3 were less than 1.0%. It should be mentioned that products in which R = COOH and OH were identified as methyl derivatives; diazomethane was used as the methylating agent.

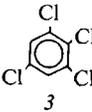

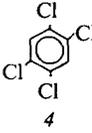

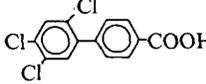

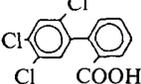

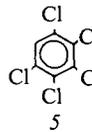

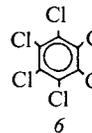

Tables 1 and 2 indicate that among the PCBzs investigated, hexachlorobenzene (6) was unique in not generating products via Reaction 1. Recently, Choudhry and Hutzinger [10] reported that Cl₆-Bz (6) does not yield PCBs, contrary to the direct and acetone-sensitized photolyses of PCBzs 2 to 5 in water-acetonitrile mixtures.

In addition to the products described above (Tables 1 to 3), irradiation of PCBzs 1 to 5 in the presence of humic model monomers 7 to 12 yielded reductively dechlorinated benzenes as the major photoproducts, along with minor products including PCBs, photoisomerized PCBzs (except from 5) and polychlorophenyl acetonitriles. No attempt was made to quantify these additional photoproducts. However, complete quantitative data for such photoproducts arising from nonsensitized and acetone-sensitized photoreactions of

1,3,5-Cl₃-Bz (1) [9] and PCBzs 2 to 6 [10] have been published previously.

The 16-h exposure of Cl₄-Bz 4 in the presence of vanillic acid (9) led to the production not only of photoproducts formed through Reactions 1 and 2 (Fig. 1) but also of mono- and dichlorodibenzofurans having carboxylic and methoxy substituents formed via secondary photoprocesses (Table 3). The photolytically induced reactions of 4 with humic model monomer 9 are suggested in Fig. 2. Photoexcited tetrachlorobenzene 4 undergoes homolytic scission of a C-Cl bond, which produces 2,4,5-trichlorophenyl radicals (13) (step a, path i), together with photoisomerization to eventually generate Cl₄-Bzs 2 and 3 (step a, path ii). Secondary photolyses of these photoisomerized tetrachlorobenzenes generate trichlorophenyl radicals 14 and 15 from 2 and 16, 17 and 18 from 3 through the homolysis of the appropriate C-Cl bond. The mass spectral detection of trichlorophenylacetonitriles and all expected isomers of heptachlorobiphenyls in the case of photoreactions of Cl₄-Bzs 2 to 4 in the presence and absence of acetone as a sensitizer in aqueous acetonitrile is

For PCBzs 2 to 5, CH₃CN:H₂O (1:1, v/v) was used as the solvent system and for substrate 6, the solvent system was 9:1 CH₃CN:H₂O. Concentrations of PCBzs 2 to 6 were 1.00 mM, and each sample solution contained 5.00 mM humic monomer 8.

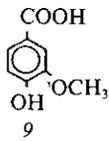

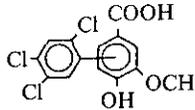

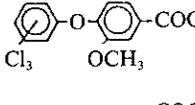

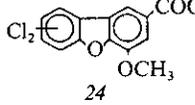

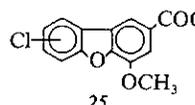

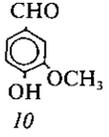

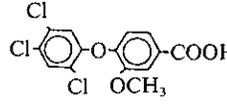

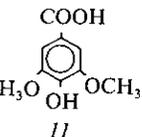

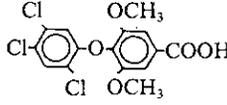

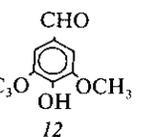

^aNumber of isomers, if any, and their percentages of total product given in parentheses.

evidence that polychlorophenyl radicals are involved [10]. Further evidence is provided by the detection of such photoproducts in the present studies.

Moreover, the photolysis of the O-H bond of vanillic acid (9) produces 2-methoxy-4-carboxyphenoxy radicals (19) (Fig. 2, step b; see below). In addition, species 19 may be pro-

duced when the hydrogen atom is abstracted from the OH group of monomer 9 by free radicals (·R) such as ·Cl, ·CH₂CN, 13 to 18 and others. Subsequently, 20 (which represents species 13 to 17) would combine with phenoxy radical 19 to yield trichloro-4'-carboxy-2'-methoxydiphenyl ether 21, containing an *o*-Cl substituent. The irradiation of ether 21 would produce 2-carboxy-

Table 3. Photochemical interactions of 1,2,4,5-tetrachlorobenzene (4) with some humic model monomers in acetonitrile-water mixtures

 12	16.0	82.1	—

The CH₃CN:H₂O ratio (v/v) for the solvent system was 1:1. Concentrations (mM) of the chlorobenzene 4 and humic monomers 9 to 12 were as follows: 4: 1.03 and 9: 4.93; 4: 1.03 and 10: 5.01; 4: 1.11 and 11: 5.06; 4: 1.08 and 12: 5.00.

dichloro-4-methoxydibenzofuran (24) through the intermediate involvement of diphenylether radicals 22 and σ -complex 23 (Fig. 2, step c). Further, photolysis of 24 would yield monochlorodibenzofuran 25. Alternatively, the product 25 may be generated

from the reductively dechlorinated diphenyl ether 21 having a 2-Cl substituent and from the appropriate photoreduced products of Cl₄-Bzs 2 to 4 and acid 9.

It is worth noting that, in similar studies,

Choudhry et al. [2] confirmed that 2,4,5-trichlorodiphenyl ether is an intermediate in the photoformation of 2,3-dichlorodibenzofuran from 4 and phenol. Species 18 also probably reacts with 19 to produce 4-carbohydroxy-2-methoxy-3',4',5'-trichlorodiphenyl ether (not shown in Fig. 2); however, this product is not expected to yield 24. Our recent investigations [19] of the photolysis of tetra- and pentachlorophenols led us to conclude that phenoxy radicals produced through the photo-

homolysis of the OH group and by other free-radical processes in water-acetonitrile will not generate products arising from the phenoxylation of a benzene nucleus. Finally, trichloroarylation of acid 9 by radicals 20a (which represent species 13 to 18) produces 26 (Fig. 2, step d). Whether intermediate 26, having a 2-Cl substituent, is also involved in the generation of 24 remains unknown.

As mentioned previously, because authentic standards are unavailable, we have been unable to

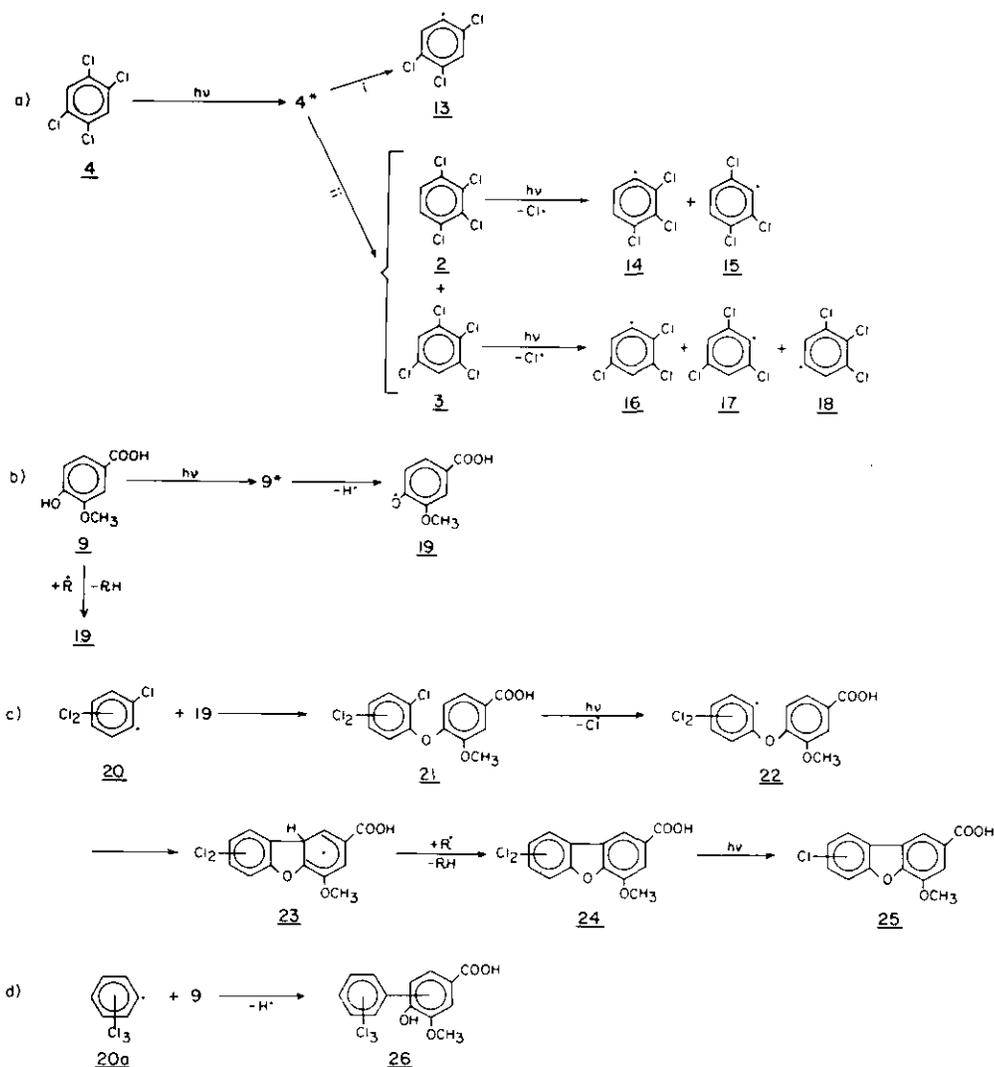

Fig. 2. Mechanism of photoincorporation of Cl_4 -Bz **4** into humic model monomer **9**.

ascribe exact isomeric structures to the photo-products, such as compounds **21** and **24** to **26** (see Fig. 2). However, the structures 2,4,5-trichloro-4'-carboxyhydroxy-2'-methoxydiphenyl ether and 2,4,5-trichloro-4'-carboxyhydroxy-2',6'-dimethoxydiphenyl ether were assigned to products formed in the photoinduced interaction of Cl_4 -Bz **4** with vanillin (**10**) and syringic acid (**11**), respectively (see Table 3). The probability of radical **13**'s contributing to Reaction 2 (Fig. 1) is greater than those of radicals **14** to **18**. Moreover, only one product of this sort was observed for each photoinduced reaction of **4** with **10** and **11**. It is noteworthy that in the

case of UV exposures of **4** containing syringaldehyde (**12**) the anticipated photoinduced products were not seen even when 82% of the initial chlorobenzene had disappeared (Table 3). Furthermore, during the photoincorporations of PCBzs **2** to **5** into benzaldehyde (**8**) (Table 2) as well as of **4** into vanillin (**10**) (Table 3), the aldehydic group on the nucleus of humic monomers and/or those of the photoproducts were photooxidized into carboxylic acid groups. Choudhry et al. [19] elsewhere reported such photooxidations of halogenated benzaldehydes.

During the photochemical interactions of 1,2,

based on GC-MS data and are therefore tentative, the photoincorporation of PCBz into the humic monomers investigated appears to occur through intermediate polychlorophenyl radicals. These relatively long-lived intermediate radicals, produced from PCBz in the aqueous environments and possessing characteristics similar to those of H₂O-CH₃CN mixtures, are likely to interact with the free-radical centers of humic substances, such as fulvic acids, humic acids and humins. It is noteworthy that humic macromolecules are known to possess free-radical characteristics, having 10¹⁷ to 10¹⁸ spins/g [5,7,21]. However, PCBz may sorb onto humic substances and the light absorption spectra of the resulting complexes may differ from those of unbound (free) chlorobenzenes, whereby the nature of photoproducts and rates perhaps will change. Finally, radical species from PCBz may also react with other substituted benzenes derived from humic substances and lignins [5-8].
